Abstract: Demographic changes in the 21st century, increased population of the elderly and high prevalence of related diseases call for new healthcare strategies that can change the behavior and lifestyle of elderly individuals. Innovative information and communication technology, such as mobile health (mHealth), can play a significant role. The present study was conducted aiming to assess the effectiveness of mHealth in improving health behaviors among an elderly population. This paper presents a systematic review involving a search of PubMed, Web of Science (ISI), Scopus, Science Direct and Embase databases from [2012–2016]. Our search resulted after initial evaluations 12 articles. Inclusion criteria mostly revolved around interventional studies, other studies were excluded because of their methodology, non-elderly target groups and irrelevant to the subject. Findings showed that mHealth can improve care, self-management, self-efficacy, behavior promotion (quality of sleep, diet, physical activity mental health) and medication adherence. The mHealth technology has proven effective for disease prevention, lifestyle changes, management of cardiovascular disease and diabetes, and is a suitable tool for elderly people. In conclusion, it seems that mHealth can facilitate behavioral changes; although, further research is necessary in this regard.

Introduction

Aging is a universal phenomenon expected to continue existing for the time being. By 2013, approximately 841 million individuals (11.7%) had passed the age of 60 (1). Social experts in geriatric fields have remarked that functional aging includes three interconnected processes. The first process involves physical aging, i.e., the undesirable changes happening to the body over the passage of years. The second process, psychological aging, comprises the processes caused by personality growth and development, such as emotional, cognitive and behavioral changes. Social aging, as the third process, covers the various stages of transition from one social base to another which a person experiences during a lifetime. The aging process will never stop, and only through a lifetime of healthy behavior and special health precautions can we turn this period into a pleasant, joyful and healthy time (2). There has been a global increase among the population of elderly adults in regard to prevalence of non-communicable diseases (NCDs), disabilities and other health problems, which in turn has increased the burden imposed on the healthcare system in both public and private sectors (3). Previous studies on the health status of elderly populations indicate significant changes in their conditions; in this regard, most elderly individuals had around one or two illnesses (4). These diseases are associated with lifestyle and...
form the most significant challenge the elderly have to face. According to reports from the World Health Organization (WHO), about 60% of people’s quality of life and health depends on their lifestyle and personal behavior; they have also associated 53% of the fatality causes with lifestyle and health behaviors; therefore, elderly individuals who adopt health improving behaviors would experience a healthy old age (5). Furthermore, there is an evident need in this age-group for education on healthy behavior, self-care and lifestyle changes. The demographic changes in the 21st century call for new strategies in relation to education, treatment and healthcare. Generally, innovative information and communication technology can play a significant role in caring for elderly patients, at their own homes or at other healthcare environments. In recent years, there have been many cases in which mobile health (mHealth) was used, in addition to conventional education, aiming to increase efficiency. mHealth tries to provide medical services using the capabilities of mobile technology (i.e., mobile phones) for reporting health information, monitoring clinical signs and enabling direct supervision and instruction (6). A study in the United States showed that 75.9% of the individuals over 60 years old own personal mobile phones (7). There is clear evidence that in Asia and the Pacific Ocean combined, 3.6 billion people possess mobile phones. Moreover, an increasing number of elderly individuals register for mobile phones every day (8). Research shows that the elderly population are interested in using mobile phones, as this technology and its specific characteristics can provide them with useful information, particularly relating health (9). Also, short message services (SMS) are more popular among the elderly due to their low requirements for technology skills (10). Receiving medical and educational services and adhering to clinical instructions pose a great challenge to elderly individuals living at their own houses. The important question here is: can the mHealth technology help us improve the elderly’s health behavior? Therefore, this study was conducted attempting to assess the effectiveness of mHealth in changing health behavior and improving disease recovery in an elderly population.

**Methods**

The present study is a systematic review involving a search of the well-known databases: PubMed, Web of Science, Scopus, Science Direct and Embase, with the search strategy: “mHealth or Telemedicine and Aged/Field ‘Title/Abstract’”. Our search scope covered the previous 5 years, meaning 2012–2016. Inclusion criteria for the studies involved use of mHealth for promoting health behavior in elderly populations (age of 60 and over), with a main focus on authentic experiments and clinical trials. Criteria for exclusion were irrelevance to the main subject, younger age-group, methodology, study design (review article, descriptive, cross-sectional study, survey research) and lack of originality. Initially, 1,294 articles were found in all databases, which after limiting the search to publication date, language (English articles) and design (interventional studies), 674 articles were selected for initial evaluations by one reviewer. Eventually, 12 papers were determined suitable and compared against the PRISMA-P 2015 checklist (Figure 1) (11).

**Results**

The findings of this study including psychological health behaviors change through mHealth [3] physical activity and dietary behavior (increased consumption of fruits & vegetables) and monitoring for high blood pressure, high blood glucose [6], chronic illnesses such as diabetes and heart disease [6]. The articles under study had all used the mHealth technology to study topics such as behavioral changes related to sleep and relaxation, impact of self-monitoring activities, self-efficacy, quality of life and depression on survival of elderly cancer patients, Fitbit-based physical activity and its development in adults with cognitive disorders such as Alzheimer’s (accelerometer), caring for diabetic foot ulcers (reminders for use of thermometer and instructions for care), adherence to medication (electronic blisters) and treatment, and recovery of elderly patients with cardio-metabolic disease, hypertension and acute coronary syndrome. Their procedures involved frequent text messages and calls, as well as use of mobile applications and smart games for reminders, education and reporting to the nurse, all toward promotion of health and healthy behavior (Table 1). Methodology and features of studies to mHealth application, sample size, interventions, outcomes are summarized in Table 2.

Aikens et al. study for patients with diabetes that received weekly interactive voice response (IVR) calls about assessing health status and self-care, and showed that health and self-care problems were strongly interrelated within IVR calls. Patients who reported hypoglycemia symptoms were highly likely to concurrently report blood glucose levels <90 mg/dL [odds ratio (OR)=8.24, 95% confidence interval (CI): 5.70–11.90, P<0.001] and self-treatment of hypoglycemia (OR=67.05, 95% CI: 46.2–97.3, P>0.001) (12).
Martin et al. research about automated mHealth intervention for physical activity promotion, reported the primary outcome was differential in activity levels was significant; participants receiving texts increased their daily steps over those not receiving texts by 2,534 (95% CI: 1,318–3,750; P<0.001) and over blinded controls by 3,376 (95% CI: 1,951–4,801; P<0.001). Secondary outcome the unblinded-texts group increased its total activity time by 21 min/day (23% increase) and aerobic time by 13 min/day (160% increase), which was statistically significant compared to the other groups (13).

Buman et al. designed a community-embedded iterative framework, multicomponent smartphone application (app) that change target behavior. Participants aged 35–60 years, who were measured as overweight/obese [body mass index (BMI) ≥25 kg/m², glucose of ≥100 mg/dL]. After 8 weeks, results across both the sleep and sedentary components were the enhanced self-awareness of the participants’ behaviors. Overall satisfaction was modest (14).

Lazo-Porras et al. research was on the individuals with a diagnosis of type 2 diabetes mellitus. Participants in the intervention arm will receive an mHealth component in the form of SMS and voice messages as reminders to assess messages impact on the improvement of foot ulcer. mHealth tool caused the promotion of healthy outcomes (15).

Petrella et al. study was a community-dwelling mHealth supported exercise. Intervention group were patients with at least two metabolic syndrome risk factors and the mHealth intervention group received a kit, which included a smartphone data portal equipped with Health anywhere, health monitoring application, a Bluetooth™ enabled blood pressure monitor, a glucometer with Bluetooth™ adapter and a pedometer. At 12 weeks, adjusted mean

RCT, randomized controlled trial; IVR, interactive voice response; BMI, body mass index; SMS, short message services; mHealth, mobile health; LDL, low-density lipoprotein.
change in systolic blood pressure (SBP) was greater in the active control group compared to the intervention group (−5.68 mmHg; 95% CI: −10.86 to −0.50 mmHg; P=0.03). Diastolic blood pressure (DBP) and waist circumference were reduced in both intervention and active control groups at 24 and 52 weeks compared to baseline (all P<0.01). At baseline and 12 weeks, fasting plasma glucose was higher in the intervention compared to the active control group (both P<0.05). Compared to baseline, HbA1c was reduced in both intervention and active control groups at 24 weeks (P<0.05), but at 52 weeks it remained lower than baseline only in the intervention group (P<0.001). At 52 weeks, low-density lipoprotein (LDL) was reduced in both intervention and active control groups compared to baseline (P<0.05), and total cholesterol was reduced in the active control group at 24 weeks (P=0.04). Triglycerides were reduced only in the active control group at 52 weeks compared to baseline (P=0.005) (16).

Brath et al. evaluated a mHealth-based remote medication adherence measurement system (mAMS) in elderly patients with increased cardiovascular risk for diabetes, high cholesterol and hypertension. The system utilized common information and communication technologies (Web and mobile phone applications) as well as embedded microelectronic components (including printed electronics) to record the timestamp and number of pills taken. A total of 654 electronic blisters were handed out. A statistically significant difference (P=0.04) between the monitoring and the control phase was observed for the diabetes medication only. P=0.02 indicates significant improvements in blood pressure (systolic and diastolic values) as well as in total and LDL cholesterol concentrations (17).

Müller et al. designed Malaysian Physical Activity for Health Study (myPAths). All participants in SMS texting arm were introduced to sets of exercises and received an exercise booklet and additional 60 text messages over 12 weeks. The other arm did not receive SMS text messages (non-SMS texting arm). During 12-week intervention period, participants in the SMS texting arm exercised more frequently per week [mean, 3.74; standard deviation (SD), 1.34] compared to participants in the non-SMS texting arm (mean, 2.52; SD, 1.50). This difference was significant (P=0.03). The effect of the SMS text messages on weekly exercise frequency was stronger after adjusting for baseline exercise self-efficacy with analysis of covariance (ANCOVA) (F 1,36=6.81, P=0.01) (18).

Vidon et al. study was designed to assess the promoting activity through clinical education and reinforcement (PACER). Nine individuals with normal cognition of baseline or maintenance and 21 individuals with Alzheimer-related cognitive impairment. Each cohort had a mHealth accelerometer-based physical activity prescription to double number of steps taken. Secondary physical measures included the 6-minute Walk Test (6 MW), mini-Physical Performance Test (mPPT). The cohort with normal cognition did increase their weekly step count above week 1 (P=0.05, 95% CI: 0.0–0.8). And cognitive impairment did not significantly change their weekly step count above week 1 (P=0.21, 95% CI: −0.2 to 0.7) (19).

Nelson et al. patients with T2DM participated in a mHealth intervention called messaging from a mobile communications platform. Compared to whites, non-whites had a 63% decreased relative odds [adjusted odds ratio (AOR)=0.37, 95% CI: 0.19–0.73] of participating in calls. In addition, lower health literacy was associated with a decreased odd of participating in calls (AOR=0.67, 95% CI: 0.46–0.99, P=0.04), whereas older age and more depressive symptoms (AOR=0.62, 95% CI: 0.38–1.02, P=0.059) trended toward a decreased odd of responding to texts. Participants’ race was significantly associated with IVR call participation (P<0.01). Compared to white participants. Depressive symptoms were marginally associated with the probability of text responses (20).

In the research from Rubinstein et al., patients with SBP and DBP between 120–139 and 80–89 mmHg was selected. Participants received either monthly motivational counselling calls and weekly personalized text messages to their mobile phones about diet quality and physical activity for 12 months, or usual care. Intervention did not affect change in SBP (mean net change, −0.37 mmHg; 95% CI: −2.15 to 1.40 mmHg; P=0.43) or DBP (mean net change, 0.01 mmHg; 95% CI: −1.29 to 1.32 mmHg; P=0.99). However, there was a significant net reduction in body weight [−0.66 kg (−1.24 to −0.07); P=0.04] and intake of high-fat and high-sugar foods [−0.75 (−1.30 to −0.20); P=0.008] in the intervention group compared with the control group. Participants in the intervention group who received more than 75% of the calls (9 or more, from a maximum of 12) had a greater reduction of body weight [−4.85 (−8.21 to −1.48)] and waist circumference [−3.31 (−5.95 to −0.67)] than participants in the control group (21).

In a study from Knight et al., older adults were randomly assigned to receive a personal activity program targeting changes to either daily exercise, sedentary behavior, or both at home during the 12 weeks. All participants received...
an mHealth technology kit including: smartphone, blood pressure monitor, glucometer, and pedometer. There were no differences between groups at baseline (P>0.05). The intervention had a significant effect [F(10 488)=2.947, P=0.001, η²=0.057], with similar changes across all groups for physical activity, body weight, and blood pressure (P>0.05). Changes in blood glucose were significantly different between groups, with groups prescribed high-intensity activity (i.e., exercise) demonstrating greater reductions in blood glucose than the group prescribed changes to sedentary behavior alone (P<0.05) (22).

Pellegrini et al. in their research showed that inactive adults with poor quality diet in The Make Better Choices 2 (MBC2) trial and mhealth intervention will maximize initiation and maintenance of multiple healthful behavior changes (23).

Discussion

Having an established educational plan, with various integrated educational strategies, would improve the quality of education. Using the capabilities of smart mobile phones, a proper educational program could significantly change the quality of behaviors associated with a healthy lifestyle. The most appropriate way to reduce geriatric problems and move closer to a successful old age is to take on a healthy lifestyle in this period. Lifestyle factors, physical activity and healthy diet in particular, are the main determinants of physiological and psychological health during old age (24). Despite the various proven benefits of physical activity, elderly people still don't exercise as much as they should (25). Using the mHealth technology alongside medical prescriptions, we can improve physical activity levels, normalize BMIs (13,16,19,26), and change inactive and sedentary behavior in the elderly population (18). The mHealth technology can help change and develop health behaviors (increased consumption of fruits and vegetables, stress management, reduced consumption of salt and improved quality of diet and sleep) and improve self-efficacy in elderly individuals with chronic disease (cognitive disorders & Alzheimer’s, heart disease and susceptibility to metabolic risk & diabetes) through text messages, voice messages, voice calls and game-based mobile applications. In upper-middle income countries, women undergoing menopause (27) and elderly cancer patients, as well, can benefit from the effects of mHealth in regard to adoption of healthy behavior and improvement of quality of life, self-regulation, self-monitoring and overall health (20). Furthermore, the mHealth technology can play the role of a reminder, which is a good strategy for adherence to treatment, improved care for diabetic foot ulcers and in-house clinical measurements (12,15,17,22). What's interesting is that the elderly population have fully accepted this technology as a tool for monitoring and changing of behavior (9), mainly because the technology and its specific characteristics have proven useful in meeting their information needs, especially in regard to health (9). There is a frequent usage of SMS among the elderly due to the low level of technology skills required for sending and receiving them (10). To present reliable, authentic and practical information relating mHealth services that can lead to improved health levels and healthy lifestyles, sampling is better done among individuals with similar physical, functional and psychological conditions, age-groups, cultural characteristics, incomes and places of residence (city, rural, etc.), so that better, more logical results are achieved; the reason we mention this is that elderly minorities and ethnic groups, people with low health literacy and depressed individuals might use this technology to a lesser degree (20). It's important to note that we can form behavior through this technology along with medical instructions and recommendations, but this might not be a stable enough option in the course of time, as it requires help from other individuals. Considering the age-related characteristics and physical capabilities of elderly people, it would be more effective to focus on one specific behavior and its related functions, so that the elderly participants can have better self-monitoring capability and the interference of multiple simultaneous activities related to behavior doesn't affect the quality and quantity of their activity monitoring and reporting. On the other hand, the direct influence of mobile technology, along with behavioral change theories, can strengthen the interventions (26).

Conclusions

Our findings indicate the effectiveness of the mHealth technology in improving health behaviors, controlling the conditions of elderly individuals, changing their lifestyles and reducing risks under chronic conditions. This technology seems to be suitable and effective for elderly people and its use could help them achieve desirable health outcomes. However, further research is required in this area.
